15. Supplementary Notes  Report covers summary results of development efforts under contract DOT-FA70WA-2253 performed by Andrew Alford Consulting Engineers Winchester, Massachusetts 01890			
16. Abstract  Federal Aviation Administration Systems and Research and Development efforts through a contract with Andrew Alford Consulting Engineers have resulted in the development of a set of ILS localizer antenna arrays of the traveling wave type. These arrays including integral monitors have been shown capable of overcoming the major shortcomings associated with earlier antennas. The results of this effort are summarized. Distinguishing performance characteristics are pointed out for each of the so-called Type O, 1A, 1B and II antenna arrays.

## 1.0 INTRODUCTION

The VHF localizer has existed in general operational use for well over three decades, as part of the ILS, to provide horizontal guidance for aircraft approaches to airports. The localizer generates a more or less directional tone modulated radiation pattern centered about a runway centerline extended to produce proportional left or right instrument deviation indications in an airborne receiver depending on the aircraft location within the localizer course sector and full scale deviating indication (called clearance) elsewhere within the localizer signal coverage. All localizers in general conform to the International Standards and Recommended Practices of ICAO Annex 10.

Since its original inception many improvements have been introduced to the system along the lines of electronics and antenna developments. The design and performance characteristics of the radiating antenna array is of special importance due to the critical necessity for accurate guidance with decreased visibility and approach minimums. A potential problem is that at many airports, the radiated signal could be adversely affected due to reflections from buildings, taxiing aircraft, etc., thus limiting the accuracy and use of the localizer during low visibility.

This report presents the results of a major development effort for antenna arrays which overcome weaknesses of existing systems and are suitable for practically all types of airport sites.

## 2.0 BACKGROUND

For a background of the development effort, it would be well to briefly summarize some of the difficulties associated with the existing localizer antenna arrays in operational use by FAA during the Fifties and Sixties, namely (1) the 39-foot aperture single frequency eight-loop array, (2) the 117-foot aperture two frequency waveguide (with its eight-loop array for clearance and backcourse), and (3) the 105-foot, single frequency, 15-element V-Ring array.

All of these arrays were developed at a time when FAA required both a front and a back course and full scale clearances at all azimuths between the front and back course sector width limits. Due to increasingly difficult siting conditions created by normal airport expansion, these arrays were hard pressed to provide Category II (and in many cases even Category I) performance. The siting problem was further aggravated by the introduction of larger and higher performance jet aircraft which required better localizer beams for operation with their couplers. None of the existing arrays were designed to take advantage of a newly implemented policy which deleted the requirements for a back course and for clearances beyond  $+35^\circ$  of the front course. Each used individual radiating elements with little or no directivity. They all suffered from now obsolete and overly sensitive monitor pick-up arrangements resulting in instabilities and susceptibility to weather. The design did not take into account overflight interference and means of minimizing it. Specific shortcomings in each array had been noted as follows:

Eight-loop array. Due to its small aperture, its course quality is not good for Category II or even Category I in many cases. Its clearances are generally marginal. The array had to be "tailored" to each site with special screening in many cases resulting in high initial installation and flight inspection costs.

Wave guide system. Initial production costs for this "brute force" type of an array as well as the costs for the "tailored" installation and flight inspection are very high. In addition, the waveguide required a separate eight-loop array for clearances and the back course.

V-Ring array. The single frequency V-ring array represented a compromise design with a complex antenna element. In spite of its complexity, it would not meet Category II requirements for course quality and clearance at many sites. It has been susceptible to severe monitor problems and suffers from the effects of mutual inductance coupling. It requires precise on-site tuning for each frequency.

Contract DOT-FA70WA-2253 was awarded on October 27, 1969, to Andrew Alford Consulting Engineers, Winchester, Massachusetts, for a theoretical design study and the development, fabrication and test of three new state-of-the-art types of localizer antenna arrays which would meet the latest operational requirements and overcome the deficiencies described above.

Some of the major provisions of the contract requirements included performance in accordance with the ICAO requirements, accommodation of the antenna arrays to any typical type of siting environment, more directive antenna elements with built-in individual monitor probes, reduced antenna element to element mutual coupling, no antenna adjustments over the frequency band, add-on capability to a given array to achieve improved performance, and maximum time delay of one second as allowance for interference caused by overflying aircraft. For the more difficult sites, the two-frequency concept was re-introduced.

This development has essentially met or exceeded all the original engineering requirements. The result has been a common traveling wave antenna element and five basic antenna arrays or combinations of arrays assembled from the common element, namely (1) the type C6-1, a six element clearance array (2) the type 0, an eight-element single frequency array (3) type 1A, a 14-element single frequency array (4) type 1B consisting of a 14-element directional array used with the six-element separate frequency type C6-1 clearance array and (5) type II, consisting of a 22-element directional array and used with the eight-element separate frequency type 0 clearance array.

The most economical selection of an array obviously requires consideration of the siting conditions as well as the performance Category (I, II or III) that is to be established for the localizer for a given site. A special study was performed by the Contractor to establish selection guidelines. This effort resulted in Report No. FAA-RD-75-64 "A Guide for the Selection of Antenna Characteristics for Single Frequency and Two Frequency Localizers in the Presence of Reflecting Structures." This report is considered an invaluable aid to the installation engineer.

### 3.0 DETAILED TECHNICAL DESCRIPTION

3.1 Antenna element. All five antenna arrays developed by Andrew Alford Consulting Engineers are made up from the same basic element, namely the traveling wave loop antenna, also called the 0 element or, by the Alford designation, Type 4770 element. See Figures 1 through 3.

The traveling wave loop antenna element consists of 15 radiating and partially overlapping rings, spaced 12.75 inches apart at the point of attachment and slanted across an open common balanced transmission line consisting of two bars terminated by a resistive load. The sending and receiving ends of the balanced transmission line are provided with baluns for conversion to unbalanced input and output terminations respectively. The output balun is terminated in a 50 ohm impedance. The spacing between the rings was chosen to produce a very low value of radiation along the back course when the element is properly terminated. The directional characteristics of radiation pattern can be seen from Figures 5, 6 and 7. It can be seen from these drawings that the radiation from the antenna is essentially unidirectional and that it consists of a single major lobe. The mutual inductance characteristics between adjacent antenna elements is excellent and is at least -34db at the minimum spacings used between elements in an array. The element which is 18 feet long (about  $2\lambda$ ) is typically mounted at a height of not over  $2/3 \lambda$  (approximately 72 inches) above ground and presents a relatively low profile and yet produces a low angle vertically directive radiation pattern.

Other electrical characteristics include the following. The overall element input impedance is 50 ohms. The element will handle a power input of up to 75 watts. The transmitting frequency capability is from 108 to 112 MHz without any antenna adjustments. The input VSWR is less than 1.1:1 over this band. The polarization is horizontal with the vertical component at least -26 db from the horizontal. The front to back ratio is 26 db+. The performance of the antenna element is not seriously degraded from icing; however, to insure no degradation of the performance and for protection of the elements, these are usually enclosed in a radome as shown in Figure 1. To monitor the power level radiated from an element, the power existing at the output termination of the element may be sampled. Samplings from each element in an entire antenna array are combined to provide an analog monitor for the entire array, as will be shown later under the discussion of monitoring of the array.

3.2 Antenna Arrays. As mentioned already, there are several antenna arrays. These are all made up from the same basic element. The arrays have been designed in such a way that regardless of the number of elements, the spacing of the two center elements are identical (i.e.,  $.6\lambda$  between each other or each  $.3\lambda$  from the middle of the array, at 110 MHz) and the spacing between all additional elements is also identical,

namely  $.75\lambda$  at 110 MHz. In all cases an even number of elements is utilized which helps the mutual coupling problem. No spacing adjustment is required for a frequency change within the band. However, each type of array requires its own power distribution scheme. Figures 10 and 11 show two types of input power distribution networks.

Five distinct arrays have been developed:

- (1) 6 elements      32-foot aperture, provides clearance radiation on a separate frequency for the 1B array (Type C6-1)
- (2) 8 elements      45-foot aperture, provides clearance radiation on a separate frequency for the Type II array, or may be used alone as a self clearing array (Type O)
- (3) 14 elements      83-foot aperture used as a self clearing single frequency localizer antenna (Type 1A)
- (4) 14 elements      83-foot aperture, directional array (Type 1B) on one frequency, used together with Type C6-1 for clearance
- (5) 22 elements      140-foot aperture directional array (Type II) on frequency used together with Type O for clearance

Table I displays antenna element spacings for each array. Tables II and III list the nominal current amplitudes and phase of the currents applied to each antenna element of each array.

\*This phase relationship applies to all values in the table.

3.3 Antenna Performance. The minimum performance array, Type 0 as described herein is self-clearing (i.e., a single frequency rf carrier provides a course as well as full clearances). It is intended for use at locations relatively free from reflection interference sources in the 180° front course azimuth sector of the array. In comparison, the 14-element, type 1A array, also self clearing, which directs a greater proportion of the radiated energy along the runway centerline, may be used at locations having a moderate extent of interfering sources in front of the array. The radiation patterns of these two arrays are shown in Figures 8 and 9, respectively.

A graphic comparison among several arrays is presented in Figure 12 which shows the relative distribution of sideband radiation versus azimuth of several arrays. Note in particular the relative amplitudes of the 8-loop array, the 15-element V-Ring Array, the Type 0 and Type 1A array. In general, the greater the relative level of off-course sector radiation the greater the potential is for a reflecting source at these azimuths to cause a reflected signal to combine with and deteriorate the signal elsewhere within the coverage including the course where beambends may be caused. The improvement made possible by the introduction of the traveling wave antenna arrays, when compared to the previously existing arrays, is obvious.

Figures 15-20 are presented to show the radiation patterns of the Type 0 array as frequency and course widths are changed from one operating limit to the other. The Type 1B (which includes the 14-element directional arrays plus the C6-1 clearance array) will provide Category II localizer course quality even at difficult sites and may also be used for Category III ILS application. A typical radiation and ddm pattern is shown in Figure 21.

The radiation pattern for the Type II array as shown in Figures 22 and 23 shows the exceptional directional course characteristics of this array. The Type II array has been proposed as suitable for application at difficult Category III sites.

To date all the types have been installed and tested, and all, except the Type II array have been put into operational commissioned use.

Each of the five separate arrays described (C6-1, 0, 1A, 1B and II) is driven by two separate input signals consisting of a modulated carrier (CS) and a carrier suppressed double sideband signal (SO), through an input distribution network. This network which is different for each array, distributes each signal to the elements in the relative nominal current ratios and phase as indicated in Tables II and III. The antenna input distribution networks are illustrated in Figures 10 and 11 for the Type 0 and Type 1A arrays, respectively. The relative ratio between CS and SO determines the course width for a single array (compare, for example, Figures 15 and 16). No backcourse is generated. When two

separate carriers are employed (Type 1B and II), the course radiation carrier predominates within the course sector and the separate clearance rf frequency carrier at azimuths beyond the capture points where the two are equal in amplitude. Any reflections of the clearance energy into the course sector is discriminated against by the so-called "capture effect" in the receiver, i.e., the non-proportional discrimination to the weaker rf signal by the predominant course rf signal. The relative power ratio of the signals to each array is adjusted to provide an overall acceptable course width and clearance. On the coursesline, the clearance carrier is nominally 10 dB below the course carrier. Figures 21 and 23 show the resultant ddm distribution from the dual frequency 1B and II arrays.

TABLE IV summarizes some additional comparison characteristics among the arrays.

3.4 Monitoring. All the antenna arrays described are provided with integral monitor pick-up systems which will supply localizer on-course and off-course status signals for conventional, i.e., typical FAA in-use monitors. The shortcomings of the monitor systems previously described such as environmental effects, overflight interference, and time delays have been eliminated by the integral monitor system. The integral monitor system effectively samples the energy radiated from each element of the antenna array and recombines these signals to accurately represent far field course, and course deviation sensitivity or clearance behavior.

The monitor combining networks shown in Figures 10 and 11 are typical for all the arrays, except, of course, for the number of antenna elements involved. In the system shown in Figure 10, the signals are sensed by eight dual couplers representing the terminal loads connected to the outputs of each of the eight-antenna elements. The coupling loss is about 14 db. A set of one signal from each coupler is taken and fed through cable lengths chosen to be of equal electrical length between each coupler and the inputs to a 9-port resistive star combiner, the output port of which represents the combined rf signal which is fed to an on-course detector. A set of a second signal from each of the eight couplers is taken and fed to the inputs of a second 9-port resistive star combiner, the output port of which produces the combined rf signal which is fed to the off-course detector. However, in the case of the signals fed to the star combiner for the off-course detector, their electrical paths are not equal. In this case, instead, for example starting with the cable from the extreme left coupler and going to the right, each successive cable is increased in length by an electrical length made equal to  $d \sin \theta_0$  where  $d$  is the distance in electrical degrees at 110 MHz between two adjacent antenna elements and  $\theta_0$  is the off-course angle at which the signal is to be monitored, typically  $2^\circ$  from the course center line. The value of  $\theta$  remains constant in a given system after it has been chosen. The combined off-course signal that is produced is essentially the same signal that would be picked up by the off-course dipole in the field at an angle  $\theta_0$  provided that the dipole were placed far enough from the array to be effectively located in the "far field," i.e., beyond  $2D^2/\lambda$  where  $D$  is

TABLE IV

Summary of Characteristics of Traveling Wave Antenna Arrays

Type	<u>0</u>	<u>1A</u>	<u>1B</u>	<u>II</u>
Aperture	45'	83'	83'	140'
Separate clearance aperture	N/A	N/A	32'	45'
Total No elements	8	14	20	30
On course aberrations due to reflection $\pm 15^\circ$ to $35^\circ$ compared to V-Ring array	2X	1X	.2-.1X	.1X
On course aberrations due to reflections beyond $\pm 35^\circ$	Unlikely problem	nil	nil	nil
Carrier beam width	$20^\circ$	$9^\circ$	$7^\circ$ (dir.)	$4^\circ$ (dir.)
SB Lobe widths	$10^\circ$	$4.5^\circ$	$4.5^\circ$ (dir.)	$3^\circ$ (dir.)
SB Lobe peaks	$\pm 8^\circ$	$\pm 5^\circ$	$\pm 4.5^\circ$	$\pm 3^\circ$
Typical power input Dir. antenna (watts)	5	5	9	6
Power input clearance antenna	N/A	N/A	3	3
Radiation beyond desired coverage sector as compared to maximum	10% @ $+40^\circ$ little beyond $\pm 50^\circ$	10% @ $+40^\circ$ little beyond $\pm 50^\circ$	(dir) 5% @ $+11^\circ$ nil beyond $\pm 8^\circ$	(dir) 5% @ $+11^\circ$ nil beyond $\pm 8^\circ$

the width of the array and  $\lambda$  is the wavelength. For a 100-foot array, this is approximately 2,200 feet from the array. The arrangement adopted for the off-course signal combiner approximates the ideal arrangement in this respect and provides a signal similar to one that would be picked up in the far field.

3.5 Field tests and implementation. At an early stage of the development effort two significant field tests were conducted, one at Tulsa, Oklahoma and the other at Boeing Field International.

The following is an excerpt from Contractor Progress Report No. 22 which covered field testing at the Tulsa International Airport in August 1971.

"The V-ring generated localizer course serving runway 35R at Tulsa, Oklahoma is very rough because of the erection of a large hangar for Boeing 747 Airplanes. Depending upon whether the doors are open or closed, the course bends vary between 45 and 60 microamperes.

The recently completed tests at Tulsa were undertaken to determine whether a CAT II localizer course could be obtained with a two-frequency system consisting of a fourteen element traveling wave course array (FAA 1B) together with an eight element (FAA Type 0) array as a clearance array, or a six element C6-1 Clearance Array.

Several combinations were tried. Every combination after some adjustment of input powers, resulted in a CAT III performance. The arrangement recommended as the result of the test consists of the fourteen element course array (FAA Type 1B) placed at 580' from the runway and a six element clearance array C6-1 placed 780' from the runway."

The field tests at Boeing Field International were conducted a year later and included testing of all the newly developed antenna arrays. The Boeing field was considered a difficult site for localizer installations as the existing localizer waveguide installation only yielded Category I course quality performance. It was found that the Type 2 (actually the same as Type II as described in this report) would provide Category III course quality. The Boeing tests served to demonstrate the relative performance capability of all the traveling wave antennas and the existing waveguide and eight loop arrays. A major excerpt of the Contractor's progress report for this phase of his development effort has been included as an Appendix to this report.

To date some 130 each type 1B systems built by Texas Instruments Inc. for the USAF and FAA have been or are scheduled for installation.

More recent development efforts by Andrew Alford Consulting Engineers under a subsequent contract have resulted in a single combined both course and clearance array with performance comparable to type 1B. Additionally, special monitor arrangements including antenna misalignment detectors and rf cable deterioration detectors have also been developed and field tested under this contract. A separate report is anticipated on these developments.

SITE TEST OF THE TYPE 2 LOCALIZER SYSTEM  
AT BOEING FIELD INTERNATIONAL  
AUGUST 22 TO SEPTEMBER 7, 1972

JANUARY 22, 1973

ANDREW ALFORD CONSULTING ENGINEERS  
149 CROSS STREET, WINCHESTER, MASSACHUSETTS 01890

SITE TEST OF THE TYPE TWO LOCALIZER AT BOEING FIELD  
INTERNATIONAL AIRPORT ON AUGUST 22 TO SEPTEMBER 1, 1972

Summary of Activity Schedule

1. Aug. 10 - 11 Pack arrays and equipment at NAFEC for delivery to Boeing Field via truck.
2. Aug. 15 Equipment arrived at facility.
3. Aug. 19 - 22 Erect temporary support structures for array.
4. Aug. 23 - 24 Install base angles and level support structures for 22 element array and 8 element array.
5. Aug. 24 Flight checks of BFI commissioning facility without test arrays erected in front.  
Erect type 0 array (8 element array).  
Flight check of BFI commissioning facility with type 0 array erected in front of wavepulse array approximately 15 feet.
6. Aug. 25 Erect 22 element array approximately 225 feet in front of wavepulse array.  
Flight check of BFI commissioning facility with 8 element array and 22 element array erected.
7. Aug. 28 to Sept. 1 Flight tests of type 2 localizer, type 1P localizer, type 1A localizer, type 0 localizer and type 0-1 localizer.
8. Sept. 6 - 7 Dismantle test arrays, pack in truck for return shipment to NAFEC.
9. Sept. 12 Arrays arrive at NAFEC.

### Summary of Test Results

The results of the recently conducted tests of the type 2 localizer array on runway 13<sup>L</sup> at Pecing Field International show that:

1. Course structure of CAT III quality was obtained.
2. Minimum clearance with the type two course array @, rating in wide alarm ( $0.2^\circ$ ) was 240 micro-amperes.
3. Usable distance for the Pecing Field site was obtained using 3.0 watts input to the 8 element clearance array, and 0.2 watts input to the 22 element course array.
4. Flight tests of the type 1B localizer, the type 1A localizer, the type 6 localizer, the type C6-1 localizer, and the IPI commissioned facility were also conducted. Data on these tests is included in the report.
5. Satisfactory results were also obtained with the clearance array moved to 75 feet behind the course array.
6. Special tests to show the effect of moving vehicle 75 feet in front of the course array were conducted. The data shows that the effect of the station wagons driven out on the runway at distances around 75 feet in front of the array was very small.
7. Vertical polarization effect for all arrays tested was found to be well within CAT III requirements.

TYPE 2 LOCALIZER SITE TEST AT BOEING FIELD INTERNATIONAL AIRPORT

A. Introduction

In accordance with the requirements of FAA Contract DOT-FA-7-SEA-2253, we have tested the type 2 localizer at a "problem site." The airport which was chosen was Boeing Field International Airport, Seattle, Washington. The localizers were erected on runway 13R for the tests.

The recent series of tests were conducted between August 23, 1972, and September 1, 1972.

By arrangements made by the FAA, the arrays were transferred to Boeing Field from NAITC, and returned to NAITC, by truck. Temporary wooden decks on which to erect the arrays and engineering assistance was provided by the FAA Northwest Region.

The assembly of the arrays was performed by Alford personnel assisted by personnel from FAA Washington, D.C. and Seattle, Air Force, and the Texas Instruments Company. Flight checks were coordinated by engineering personnel from the Northwest Region.

Flight tests were conducted by WE-FIN-3 SEA. FAA Aircraft N11, a DC-3, was used for all tests. FAA personnel from the Airway Facility Sector, Seattle, Washington also assisted in the erection of the arrays as well as participating in the test of the arrays. The cooperation and assistance during the tests by FAA personnel and non-FAA personnel was considerable. A list of the personnel participating in these tests is given on the last page of this report.

The tests are believed to have been successful and have provided much useful additional operating information on the family of arrays designed under the IAA Contract. A substantial portion of the measured data has been included in this report. A complete list of all flight tests is given in Table I.

#### B. Test Location

The tests of the type 2 localizer at Boeing Field were performed with the arrays installed in line with runway 13R. Xerox copies of photographs, Dwg. A332-5002 and 332-5003 show the two arrays erected at Boeing Field International (BFI). Dwg. 332-5002 shows the 22 element type 2 course array, and Dwg. 332-5003 shows the eight element clearance array.

The arrays were installed on temporary wooden decks. The platform consisted of 4" X 4" timbers and 2" X 12" X 17' planks. The temporary wooden decks were assembled directly on the ground and were leveled as required. The erection, leveling and aligning of the temporary decks was coordinated and performed by IAA personnel.

The ground between the BFI commissioned facility and the stop end of runway 13R is reasonably flat and level so that the height above ground of the two arrays was approximately the same. The height of the radiating elements above ground was approximately 112 feet. There were no permanent obstructions located between the test area and the stop end of the runway.

The test arrays were initially erected in front of the BFI commissioned localizer as shown on Dwg. A332-5001a. Tests were also made with the eight element clearance array moved forward so that the

spacing between the course array and the clearance array was approximately 75 feet. This condition is shown by a dashed line on Dwg. A332-5001B.

To move the 2 element clearance array forward, the temporary wooden platform was disconnected at the center of the deck and each half of the array was carried forward as a whole. The temporary wooden deck was bolted together again at the new location and the array was made reasonably level.

No attempt was made to realign the array very accurately.

The alignment and the centering of the eight element array with respect to runway centerline was done by tape measure and by eye. For a clearance array application, and for the tests that we were making, there was no need to locate this array with any greater precision.

### C. Test Considerations

#### 1. Site Selection

The selection of Boeing Field as the location for the type 2 localizer tests was made on the basis of the following considerations:

- a. Reflections from hangars and the surrounding hillsides result in CAT I course quality even with the standard FAA type 2 localizer. (Boeing Field is indeed a problem site that would require the type 2 localizer if any upgrading of performance category was desired.)
- b. The airport handles little of large jet traffic so that the delays and interference with the test schedule would be small. (This was indeed the case. Except for two or three landing

and take offs by "large" jets, no delays due to other aircraft were encountered. Furthermore, it is believed that our testing did not result in any delays or inconvenience to the airport.)

- e. As an additional benefit, the FAA Flight Test Operations WF-F100-3-CFA are based at Rudder Field. (This was very convenient because it provided more time to arrange and discuss test schedules and test readiness.)

## 2. The Array - Table I.

The testing involved the flight check of the commissioned facility and of all presently considered "standard" combinations of the new family of HPS arrays. A complete list of the flight tests is given in Tab. I, sheets 1 through 9.

Because of the fact that all of the HPS arrays developed under the contract use the same radiating element and because the array is built around a common center core of elements, any array can be constructed by adding to or by subtracting from an existing array. The array elements are individually known as translatable elements. For example, with the 22 element core of array size 11, one takes away the 22 element distribution network and replace it with the 16 element distribution network, connecting it to the 14 innermost elements of the 22 element array. There is no need to take down the remaining elements because there is practically no interaction between the elements. In this way, one can quickly construct and test the 16 element core assembly of the type HPS array. Using the same 14 innermost elements, one can also use a different type of 16 element distribution network and obtain the self-collimating 16 element type IA array. This procedure

continued and the innermost 8 elements can be connected as the self-clearing type 0 array or as the 8 element clearance array (as in the type 0 array) and with the 22 element coarse array in the type 2 localizer. As a final degree of flexibility, at this time, one can use just the inner six elements of the larger array and with the six element distribution pattern, test the type 0-1 array. The type 0-1 array is normally used in the cleanup array in the type 1b localizer.

At Boeing Field, a complete type 2 localizer consisting of a 22 element coarse array and an eight element clearance array were erected. The type 1b localizer was tested using the inner 14 elements of the 22 element array and the inner six elements of the eight element array. The type 0 array and the type 0-1 array were tested using the inner 14 elements of the 22 element array. The extra unexcited elements which result when smaller arrays are tested by exciting the inner elements of a larger array were left terminated in load resistors. The test results do not indicate any distortion of the LF pattern for the smaller array combination as a result of the extra elements being excited.

Any number of sizes of the combination of arrays will be able to be erected with the present facility. Other combinations, such as, for example, 14 element clearance array with either a 16 element coarse array, or a 22 element coarse array may have their own individualized different sites. Still other variations would allow the coarse array to be placed either in front of the coarse array or to the rear

of the current array. The distance "d" shown in Fig. A-2, 1.65 yards, on the test range at Brooks Air Force Base, could be as small as 10 feet. The following field for test flight would include the ground clutter factor. It is not anticipated, of course, that the aircraft will fly low on the instrumentation performance.

The calculated field patterns for the individual arrays are shown on Figs. A-3 and A-4, 12 elements, 100°, and 80°. In addition, the calculated patterns for the type 1A and the type 1B localizer systems are shown on Figs. B-1 and B-2. The patterns shown on Figs. B-1 and B-2 were calculated for a 10:1 enhancement ratio of the current array field to the cladding current field.

Prior to any flight test of the tracking wave array, all of the antennas and cables were checked at low power by an Alford Type M Impedance and Transfer Characteristic Meter. The data for a 14 element antenna, except for minor deviation, indicated that the measured essentially the same. Prior to exciting any of the arrays for radiation, the phases and amplitudes at the outputs of the distribution networks were measured. Some of the data, on the 22-element and the eight element arrays, was measured at the output ends of the monitor cables with the arrays excited. The multistage multiplication of the signals, referred to the elements of the 22-element, the 14-element, and the type 1A array were measured at the outputs of the respective distribution networks. The measured data was in remarkable agreement with previously measured data at the terminals. A portion of the measured data is given in Fig. A-12: 50.5, -50.6, -50.0, -50.2, 10.0, -50.0, -50.1, -50.2, -10.1, and -50.6.

### 3. The Transmitter

The transmitter used for the tests was the BFI facility transmitter. For the most part, all of the flight tests on the developmental landing array were made using transmitter No. 1. Tests made on the BFI facility were made using both transmitters. The percentage of modulation, as determined by periodic checks throughout the test period, was maintained between 10.5% to 20.5%.

The BFI facility was put back on the air every day following our flight checks. Connection to the BFI facility was made through a junction box located near the eight loop array and a second junction box located near the waveguide. The available power at these points was approximately 43 watts for the clearance array and 91 watts for the course array. Required cable lengths, attenuators and adjustable power dividers to reduce the power to the desired levels for the developmental arrays was planned for and supplied by AACE so that no transmitter changes or transmitter adjustments were required.

### D. BFI Commissioned Facility Considerations

The commissioned localizer facility at Iceing Field International consists of an FAA waveguide course array and an 8 loop clearance array. The approximate geometrical relative slip between the two arrays, the test array, and the runway 13R is shown in Fig. 43-2-37. Approximate input power at the course array is 91 watts and the approximate input power at the clearance array is 49 watts. Note, a course width for this facility is approximately 4.0°. The facility was commissioned in January, 1962. At that time, the facility was restricted in use to 74% of the front coverage. The facility in blocker of 136° was further restricted in use to

$\pm 35^\circ$  of the front course. The restriction is due to low clearance which occurs at and  $\pm 30^\circ$  on the  $90^\circ \sim$  side of the runway. It is not known what occurred to initiate the additional restriction. The clearance on the  $180^\circ \sim$  side of the rear section kept out beyond  $60^\circ$ , while in the extant of one station at a 1500 foot altitude. Other clearance data taken at a 3000 foot altitude would indicate that no open clearance on the  $180^\circ \sim$  side could even be extended out to  $\pm 15^\circ$  of the front course. This lack of open altitude for the middle of 1500 feet above M.L.

The clearance trends on both the  $30^\circ \sim$  and  $180^\circ \sim$  sides of the course do contain considerable scalloping, approximtely 30' M.A. on the  $90^\circ \sim$  side and approximately 60' M.A. on the  $180^\circ \sim$  side. This scalloping is believed to be due to fullfilling required turns. This in one case, and from the very extensive hill-like location on the  $90^\circ \sim$  side. The scalloping on  $180^\circ \sim$  side of the course is limited to approximately 6' from the front course and is limited to just beyond the  $35^\circ$  authorized vector. The scalloping at the  $90^\circ \sim$  side of the course is most evident around  $70^\circ$  from the front course and out around approximately 30' to 50' from the front course. In the other sections, on the  $30^\circ \sim$  side of the course, between approximately  $15^\circ$  to  $45^\circ$  of the front course, the scalloping appears to be dependent because of a peculiar characteristic of the solid state receivers in the air rafts. These receivers saturate at approximately 280 A.C. but only when the signal is modulated predominantly by 30 Hz.

This particular receiver characteristic was not considered detrimental for the purpose of the present test because the allowed clearance for all of the test courses which were well above the required

levels. If one wished to investigate the sources of reflections causing the scalloping in more detail, or indeed the maximum level of elevation on the 800' side of the course, one could, as Mr. H. L. Howell of VFWFEC 3MM correctly observed, excite the array with power - a setting.

From initial flight checks of the type 2 localizer at an elevation of approximately 300', it was determined that the radiated patterns were essentially symmetrical.

In contrast with the scalloping of the clearances produced by the 8 1/2 ft PFI clearance array, the scalloping observed using either the type 0 clearance array or the type 6 1/2 clearance array was approximately 10 mca on the 800' side of the course and approximately 30 mca maximum on the 1100' side of the course. The considerable difference in the levels of the scalloping is due in part to the fact that the signals of the test arrays are contained within approximately 10° sectors centered on the front course. The signal radiated by the eight loop clearance array is believed to be more or less uni-directional and, therefore, illuminates more of the available reflecting surfaces.

Fig. 332-501b shows a top view of the buildings and terrain surrounding the Boeing Field. Fig. A332-501b is a portion of the 7.5 minute G-squared survey map entitled "Seattle South, Washington, Quadrangle, published 1968."

The present course quality of the BM facility according to the FAA specification is CAT I quality, see Table V.

## H. Measuring and Evaluating Effect of Test Arrays Located in Front of BFI Localizer

### BFI Localizer

Because the Boeing Field facility serves as an emergency runway for the Seattle-Tacoma International Airport, it was necessary to know to what degree the test arrays, mounted in front of the BFI facility would interfere with the quality of the guidance signal provided by the BFI facility. This information was also required for Boeing Field use since the BFI facility was to be placed back in service each day following the tests of the developmental arrays.

It had been previously observed during the type 0 array tests at Harrisburg that essentially no interference with that facility resulted when the type 0 array was mounted approximately 125 feet in front of the FAA waveguide course array. In the Boeing Field tests, however, the type 0 array, at least during the first portion of the test program, had to be located approximately 135 feet in front of the waveguide array. A comparison of the 6 NM clearance orbit data and a comparison of low approach data with and without the test arrays in front of the waveguide array did not indicate any discernable interference. See data for runs 2, 5, and 19 in Table II and data for runs 3, 4, 11, 13, 18, 19 and 16 from Table V.

As a result of comparison of the measured data obtained with and without the type 2 localizer in front of the BFI localizer, it was the opinion of WD-FID-3-FA and of the engineers from the FAA and AACM, that no significant degradation of quality to the BFI facility had occurred. The BFI localizer was, therefore, put back into normal service during all flights when the developmental arrays were not being tested.

E. Clearance Orbit - Table II

For all test configurations, 6 NM clearance orbits were flown at 1500 ft above M.L. for a minimum  $\pm 35^\circ$  sector from the front course. A summary of the results of these clearance orbits are given in Table II. The minimum clearance measured within the  $\pm 35^\circ$  was 200 ft. with the type 1B array. This array, however, is designed to start cutting off close to  $35^\circ$  so that an error in angle of  $2^\circ$  or  $3^\circ$  could mean the difference between indicated clearances of 200 ft. at  $35^\circ$  in one case to perhaps as high as 330 ft. in another case. Previous flight data taken on the type 1A array at KAFEC does show the sharp cut off in the clearance quite clearly. The data from KAFEC show clearances as high as 325 ft. at both  $\pm 35^\circ$  and  $\pm 30^\circ$  on the same orbit.

It was found during the reduction of the site test data that in some cases the marks indicating  $\pm 10^\circ$  or  $\pm 35^\circ$  were not always symmetrical with the crossover point. It was also observed that on consecutive runs or successive runs of essentially the same test that the clearances at the indicated angles did not always agree. This phenomenon has been observed on a number of previous test flights. It would appear as if a sudden tail wind or an increase in aircraft speed caused the aircraft to traverse one portion of the sector faster than another equal portion of the sector. This effect would make the angle markings on the recordings look unsymmetrical. Another possible cause is slowness of the AVC circuit. In other cases, small errors have occurred in the marking on the recording of the angles from the course because ground points were used. In reducing the data, some

subjectivity is involved in determining the angle.

Data for portions of some 6.0 NM orbits are shown on Figs. A332 thru -361A, -361B, -361C, and -362D. These drawings show a portion of the orbital recording respectively for runs No. 2, 15, 36, 48, and 13. Figs. 2 and 13 show the RFI waveguide localizer clearance with and without the type 2 localizer mounted in front. Fig. 36 shows the clearances for the type 2 localizer "in wide alarm." Run 47 and 48 show the clearance for the type 1B localizer i) with a 200 ft separation between the course array and the clearance array and, ii) for a separation of 75 feet between the course array and the clearance array. It should be recalled that in both cases, the six element clearance array for the type 1B 1 calibrator is firing thru 22 elements and not thru 18 elements as would be the case in a standard 1B installation. No difference in performance, however, is expected.

#### G. Usable Distance - Table III and Table IV

Usable Distance data was recorded for all test configurations of the developmental localizers. The data was taken at an elevation of 1500 feet above M.L at 10 NM and at 18 NM or farther. The 18 NM data was recorded to determine performance at +10° off the front clearence.

A definition of the "usable distance" is given in the "United States Standard Flight Inspection Manual" OA P 8200.1 CH617 of August 26, 1970. It is cited here in substance for reference: within the usable distance the input RF signal strength at the receiver shall be at least 5 microwatts and will result in a flag alarm current of at least 240 micro amperes.

The usable distance data measured at Boeing Field is presented in Table III and Table IV. Data for both receivers is given. The flag currents are given in Table I. Minimum flag currents are given in Table I. The minimum flag current in all tests was 316 micro-amperes. The data presented in Tables III and IV show that usable distance was achieved at Boeing Field for all test configurations. It is also clear from the data, that at least at Boeing Field, because of the hills located on both sides of the runway, that input powers of 2.8 to 3.0 watts at the 8 element or 6 element clearance arrays results in acceptable signal strength levels at the test altitude of 1500 ft. above MSL.

The AGC voltages given in Table III show that the radiation patterns are reasonably symmetrical. The lack of symmetry indicated by the data given in Table IV is due to the shadow of hills in the direction of 10° on the 00 ~ side of the course. These hills, located approximately 3 NM from the localizer are approximately 275 ft. high AMSL. At 18 NM, the aircraft would be below the line sight at 1500 ft. AMSL. The reduction of signal in the direction of 10°/00 ~ at 18 NM compared to the signal in the direction of 10°/150 ~ (also at 18 NM) is approximately 6 to 10 dB. The elevation of the terrain along the 10°/150 radial is relatively low. A portion of this hilly area is shown on Dwg. A332-5015A.

It will be observed from the data given in Tables III and IV that when the AGC voltage levels exceed those corresponding to approximately 100 microvolts or so, the agreement between the two receivers is not good. For AGC levels between about 5 microvolts and 100 microvolts, the agreement is fair. The calibration curves for the aircraft receivers used during the site test are shown on Dwg. A332-5021. Receiver No. 1 for runs 1 thru 36 was Serial No. 1061. Receiver No. 1 for runs 37

thru 76 was Serial No. 1151. Receiver No. 2 for runs 1 thru 76 was Serial No. 1105. As shown on Dwg. A312-5-1 the calibration curve is given in term of microvolts versus millimeters. The actual recording from which one reads the millimeters is calibrated so that one space equals four millimeters. Since one space on the recording is only 0.1 inch wide, it is difficult to determine the high signal level with great accuracy.

#### H. Calibration Measurement and Structure - Table V

Low approaches were made for all test configurations. A summary of the data is given in Table V, sheet 1 and 2. The data given in Table V is the maximum variation of the course, in microvolt, for four different sections of the approach path. The directions which were chosen for this presentation do in order of increasing distance where the maximum course tends occur. At Boeing Field, the location of buildings and of other reflecting surfaces are such that the course tends occur in three sections of the approach path: a) threshold to -2000 ft. down the runway, b) threshold to approximately 3500 ft. in front of the runway, and c) 6000 ft. to approximately 15,000 ft. from threshold. No significant course tend were found from approximately 15,000 ft. on out.

As a reference, the criteria for specific course quality categories required by the FAA is given in Appendix A.

In the evaluation of the recorded course bend data, it was found, over the period of the testing, that the alignment of the course on a number of tests would look very good, almost dead center. On other tests, however, using the same test configuration, the recorded data would look like there was some fixed offset of the course of the order of  $4.0$  to  $6.0 \mu\text{sec}$ . The reason for the observed offset on some runs and not on others, is not known. Effects of these magnitudes are easily corrected by adjustment of the modulation balance.

Xerox copies of portions of the original recordings of low approaches on the RLU facility are shown on Figs. A3-P-002, -5020, and -5021. These drawings show relevant parts of low approaches on the RLU facility operating normally, the 6 loop array alone, and the waveguide array alone. See runs No's. 4, 6 and 8. It is seen from these recordings, that the course bends look reasonably symmetrical with runway centerline. The alignment of the RLU arrays, based on the measured data, seem to be very good. In order to verify this alignment, however, longer sections of the original recordings have to be examined. It should also be noted from these recordings, that the theodolite data becomes very rough as the threshold is approached and cannot be relied upon to describe the localizer performance. For low approaches where the theodolite is "robust", the localizer performance is determined from the "raw data" trace. The "raw data" is indeed the only signal in the recording that comes from the localizer. When the theodolite data is used, one can only extract the relative angular location of the aircraft and end up with a trace that fully describes the course radiated by the localizer. Figs. A3-P-5020 and -5021 show what might be termed very good theodolite data.

Although a large number of "coupe structure" runs were made, only a representative sample of the runs is presented in this report. Dwg. A332-502 shows a portion of a structure run with the type 0 array alone, run No. 1. Dwg. A332-502b shows a portion of the structure run for the 16-element coupe array, run No. 20. Dwg. A332-502c shows a portion of the structure run for the type 2 localizer, run No. 36. Dwg. A332-502d shows a portion of the special structure run with the type 2 localizer. During the special structure run, two station wagons were driven in front of the coupe array at a distance of  $d_1$ , approximately 75 ft., run No. 36. From the submitted data, A332-502f, or indeed from the complete recording, there is no indication that the station wagons were passing in front of the array during the structure run.

Dwg. A332-502e shows a portion of the structure run for the type 1a localizing array, run No. 57. Dwg. A332-502f shows a portion of the structure run for the type 1a localizing array alone, run No. 51. Dwg. A332-502g shows a portion of the structure run for the type 1b localizer system, run No. 61.

The measured data for the type 2 localizer does indicate that a Category III coupe quality was achieved at location 111. A comparison between the measured coupe band data for the array tested and an analysis of the site is given in the next section.

## I. Course Bend Analysis - Boeing Field International

In preparation for the site tests at Boeing Field, an initial pre-test site analysis was made to determine what sort of performance might be expected with the type 2 localizer. We wanted to know 1.) can the course quality be improved over the course quality being provided by the standard waveguide facility presently in use, and 2.) if we could improve the course quality, by how much could we improve it and 3.) could we explain to a reasonable degree of certainty why the present facility provides the course quality that it does. In addition, we were also concerned with the level of clearances that we might expect as well as what input powers might be required in order to achieve usable distance at this site. Since clearances greater than 270 micrometers for a 4.4° course width were observed in previous flight test with the type C8-1 clearance array, we did not anticipate any difficulty with the clearances. Also, since the hills around the site would dictate the required input power, the primary concern centered on the course quality that would be achieved.

In analyzing the site, we believed that the reflections on course would come from essentially three structures. These three structures, labeled A, B, and C are shown (in top view) on Fig. A332-201B. Other structures located on the field, or close to it, were considered to be either too small or to be turned in such a way that reflected beams from them would not go down on the part of the course where they would result in objectionable bends.

Structure A is the Air West Hangar. The reflecting surface of this hangar is approximately 236 feet wide and approximately 60 to 70 feet high. The reflecting surface consists of ten partially overlapping metal doors. The net width adjacent between door surfaces is approx. 16 inches.

Structure B is one of the Boeing Company buildings. This structure is approximately 300 feet wide and approximately 30 to 40 feet high.

Structure C is the Boeing Flight Center. This structure is approximately 780 to 830 feet long and approximately 110 feet high. The reflecting surface consists of 13 metal doors. Each door is approximately 60 feet wide. The closed door arrangement is such that the exterior surfaces of all the doors lie in the same vertical plane.

From a preliminary evaluation of the effect of each of the three principal reflecting sources, it is believed that because all three of these structures are essentially parallel to the runway but are located at three greatly different distances down the runway, three distinct areas of course bands may be expected. It was found from the calculations that indeed this is approximately what should occur. Building C is located at about  $5.6^\circ$  angle from the runway centerline as seen from the localizer. It is, therefore, expected to have very little effect at distances less than about +6000 feet beyond the threshold. Building B is located at an angle of  $6.3^\circ$  as measured at the localizer may be expected to contribute most to the course bands between approximately +1000 feet and +3000 feet from threshold. Building A could be expected to account for the course bands occurring between approximately -2000 feet down the runway to approximately +3500 feet.

In our preliminary estimate, we attempted to account for the course bands produced by the standard waveguide loop terminal facility presently in use. From a structure run of the waveguide

facility flight of October 1972. The maximum course bends were found to be approximately 10 microamperes. Later measurements have shown that this was approximately correct. In addition, another FISO structure run showed the effect of the eight element array alone. From the data for the eight element array alone, the course bends were found to be approximately 110 microamperes. Later measurements have also shown that this was correct as well. The maximum course bends for both runs occurred between 0 feet and +2000 feet from the threshold. The plus sign is used to indicate distances measured from the threshold in the direction away from the localizer.

Building A appeared to be a most likely source of the bends, between 0 and +2000 feet. A calculation of the maximum amplitude of the course bends due to building A assuming it to be 80 ft high, gave 17.2 microamperes for the unit localizer. A second calculation of bends from Building A also based on unit localizer, but assuming a 60 ft. height, indicated maximum course bends of approximately 6.0 microamperes. What this meant is that in order to account for the observed 110 microamperes obtained with the 8 loop array alone, the normalized sidelobedifference of the 8 loop array would have to be between 6.4 to 13.7. For the 4° measured course width, the maximum theoretical value of the normalized sidelobedifference (NSD) for an 8 loop array is only 2.5. Alternatively, if the course width of the 8 loop array was very sharp, then a large NSD would result. It also remained possible that there is a large source of reflection which was not shown on the drawings at hand. In any event, we could not, at the time, account for the measured course bends observed with the 8 loop array and had to hold off on a more detailed analysis until the additional information was gathered.

Since the NSL of the type 2 course array for a 4" course width is below .02 for angles greater than approximately  $7.0^\circ$ , we could still estimate the expected level of the course bend. Let us assume a "worst case", i.e., that the type CW-1 clearance array would result in levels around 100 microamperes. If we then adjust the input power of the arrays to achieve a capture ratio of 10 db, we could expect the course bend to be reduced to approximately +3.0 microamps. This would mean that the expected improvement in course quality would be a factor of 2 or even 3.

From the tests, it was found that we were correct in both the initial estimate and in our suspicions.

1. The course quality was improved by a 3:1 factor, and,
2. The analysis of the course bend showed that the probable source of the 110 microampere reflection is the sidehill, and not any of the buildings located in the slope area.

It was believed that if we analyzed all the structures in the field for different arrays, that by knowing the NSL's, a simple relationship could be shown to exist between the NSL's in the direction of the reflected source and the measured course bends. This was found to be the case.

Because the measured course bend observed with the 8 loop array were indeed 110 microamps for approximately a 4.00 meter course width, it was believed that the sidehill pattern may not be the same as the published theoretical pattern. The HF patterns of the 8 loop array were measured at an altitude of 3,700 feet. The theoretical patterns are plotted on chart ABP-5002. The measured patterns were plotted assuming that the losses in the distribution circuit were the sum of the line and the HF signals. We believe that this is a

correct assumption. From the measured pattern data, we were somewhat surprised to find that the maximum NSD in the direction of  $10^\circ$  from the front course appears to be about 4.4. The accuracy of the SO patterns, however, is somewhat in doubt. To partially check the measured pattern data, a comparison was made between the measured DFM observed on normal "clearance orbit" at 6 NM and 3000 ft. elevation on one hand, and the calculated DFM from the measured patterns on the other hand. Dwg. A332-5033 shows this comparison. It can be seen that the agreement between the calculated and measured DFM data is good. This agreement leads us to believe that the course width value of about  $4.6^\circ$  is probably correct. Since a course width of  $4.6^\circ$  would be inconsistent with NSD of 4.4 at  $10^\circ$ , it may be assumed that NSD value of 4.4 is doubtful.

In order to determine the relative level of course bends to be expected from each of the principal reflecting sources, we have constructed a table of NSD's for each array with an NSD value listed, based on the measured course widths, in each of the directions of the reflecting sources, "A", "B", and "C". These directions as measured from the localizer are approximately  $5.6^\circ$ ,  $6.3^\circ$  and  $8.0^\circ$ . In addition, for use later in this analysis, the maximum NSD's at or around  $20^\circ$ ,  $30^\circ$ , and  $40^\circ$  are also listed, see Table VI.

If the maximum amplitudes of the measured course bend over a section of the scanline are proportional to the values of the NSD's from a number of different arrays in a direction of a suspected reflecting object, there would be strong evidence that the suspected object is the reflecting object. A plot of the NSD's of the arrays versus maximum amplitude of the course bends should be a straight line.

Since there are several distinct groups of course bends at different distances from the threshold along the course, each group probably being produced by different reflecting objects, one has to make several plots taking NSD in the directions of the several suspected reflecting objects. Such plots are shown in Dwg.

A332-5038, -5039, and -5040. The data on Dwg. A332-5038 shows the measured maximum course bend at the distance between +6000 feet to +15,000 feet from the threshold versus the NSD's in the direction of 5.6°. The course bends at these distances seem to be fully accounted for by reflection from Building C alone located approximately at 5.6° as seen from the localizer. The agreement between the expected result based on the proportionality of NSD's and course bend amplitudes as measured is good except for some slight deviation in the case of the C6-1 and the 8 loop arrays. Dwg. A332-5039 shows the same type of comparison for the course bends at distances between -2000 ft. and 0 ft. from the threshold. For this range of distances, the course bends seem to be due almost completely to Building A. Building A is located at an angle of 8.0° from the localizer. The agreement between the theory and the measured data, except for the 8 loop array, is very good. Dwg. A332-5040 again shows the same type of comparison, as shown on Dwg. A332-5038 and -5039, but for the measured maximum course bend at distances between 0 feet and +2500 ft. from the threshold. While the course bends occurring at distances between 0 feet and +3500 feet from the threshold do come from both reflecting sources A and B, the greatest course bends occur close to the threshold. They would appear to be produced more by reflecting source A than by reflecting

source B. The NSP's shown on Dwg. A332-5040 are those in a direction of 8.0° from the localizer. The NSD values plotted on Dwg's. A332-5038, -5039, and -5040 were taken from "A Guide for the Selection of Antenna Characteristics for Single Frequency and Two Frequency Localizers in the Presence of Reflecting Structures," and adjusted for the measured course width.

It is noted in connection with Dwg. A332-5040 that again a reasonably good linear relationship exists between NSD and course bends for all of the arrays except for the type CC-1 and the 8 loop array; the agreement, however, obtained with the 8 loop array is particularly poor.

It is suggested by the data shown on Dwg. A332-5040 that an additional reflecting source, other than objects A, B and C must be present. Since there is also some disagreement for the Type CC-1 array, as well as the 8-loop array, and further, since the sideband pattern of the CC-1 array is relatively wide, one should look out beyond, say 20°, for the additional reflection source.

From the course bend recording for the 8 loop array, Dwg. A332-5023, we can determine the approximate direction of the reflecting source by measuring the distances between successive maxima of the course bends.

The approximate direction of reflecting source is given by the relationship

$$\lambda_L / \lambda_f = \frac{1}{1 - \cos \theta} \quad \text{where:}$$

$\lambda_L$  is the distance between successive maxima of the course bend in test.

$\lambda_f$  is wavelength at the test frequency.

$\theta$  is the angle measured backwards from a point on course where the course bends are being observed. We take the estimated center of the group of the course bends in question.

Performing the indicated mathematical operations, using an average spacing between the course bend maxima (approximately 600 feet) centered around a point approximately +800 feet from threshold, we find that the additional reflecting source should be in a direction of approximately 10° from the runway centerline as measured from the point located at +800 feet from the threshold. The direction of the source is shown by the "direction arrow" on Fig. A332-5015. Even when the direction of the source is known, there is still a problem to determine what this additional source really is.

If we look back from +800 ft. at an angle of 10° on the 150 cycle side, no significant reflecting source is found. If we look back from +800 ft. at 10° on the 90 cycle side, the direction arrow goes right through reflecting source A. We cannot, however, conclude that we are completely in error with regard to source A for one array and, at the same time, be correct with regard to source A for five or six other arrays. We conclude that there must be an additional reflecting source beyond source A and that this source is closer to the localizer.

If we look for the probable sources of reflection in the indicated direction, we find two candidate sources:

1. An extensive array of telegraph wires located approximately 30 feet above ground and running parallel to the railroad tracks shown on Fig. A332-5015.
2. A relatively broad sloping hillside rising 70 to 80 feet above the runway and extending for a distance of approximately 3000 ft. The hillside of interest is located at angles between 20° and 45° from the localizer. A portion of this area has been enclosed by a dashed line and designated as source F, see Fig. A332-5005.

It may be assumed that the reflection from the telegraph wires 30 feet high would be less than from a flat metal wall 30 feet high. Assuming such a wall 6000 feet long, we find that the reflection from this wall when it is illuminated by an 8-loop array would produce bends around 2.0 microamperes, and not 110 microamperes. The telegraph wires, must, therefore, be dismissed as a possible candidate. This leaves only the hillside and a substantial row of trees on the hillside as the only possible sources.

### J. Vertical Polarization Measurements

Vertical polarization was measured on the Type 0 array, Type 2 System, and the type 1B System. The measurements were made on the inbound portion of course structure runs No's 18, 33, 34, 40, 48, 61, and 68.

The effect of the vertical polarization as shown on the recordings for the runs given above appear as a slow change in course direction. No sudden displacement of cross pointer indication was observed on any of the vertical polarization checks.

The maximum value of course shift that was observed for a standard  $\pm 20^\circ$  wing dip was  $\pm 4.0 \mu\text{a}$ . This variation was observed during the inbound portion of structure run No. 34 on the type 2 localizer system. The portion of this run showing the vertical polarization check is given on Dwp. A332-5041. Other measurements of the vertical polarization for the same type 2 localizer, runs No. 33 and 68, however, showed a negligible vertical polarization effect.

The maximum vertical polarization effect that was measured with the type 1B localizer system was  $\pm 2 \mu\text{a}$ . The vertical polarization effect with the 1B course array alone, run No. 40, was less than  $1 \mu\text{a}$ . Since these arrays are all constructed from the same type of element, one would not expect to find any significant differences in the vertical polarization effect for different arrays.

The FAA Specification on vertical polarization effect is given below: United States Standard Flight Inspection Manual, "F-100.1, CH 17, 8/26/76, br. 11V-4. (1) 1.1 LOCALIZER. The maximum displacement of the course line due to vertical polarization effects shall not exceed  $15 \mu\text{a}$  for Category I or  $18 \mu\text{a}$  for Category II facilities."

## COURSE BEND CRITERIA

### CATEGORY I.

Maximum variation of course indications from runway centerline starting from the ILS reference datum\* (100 ft. above threshold) to 3500 ft. from threshold is  $\pm 15 \mu\text{a}$ . From 3500 ft. to 4 NM, the maximum variation is allowed to increase linearly from  $\pm 15$  to  $\pm 30 \mu\text{a}$ .

### CATEGORY II

Maximum variation of course indicator from runway centerline starting from the ILS reference datum to 3500 ft. from the threshold is  $\pm 5 \mu\text{a}$ . From 3500 ft. to 4 NM, the maximum variation is allowed to increase linearly from  $\pm 5$  to  $\pm 30 \mu\text{a}$ .

### CATEGORY III.

Category III encompasses Category II and in addition provides that the maximum variation of course indicator from the ILS reference datum (100') to a point 20 ft. above the runway and 2000 ft. down the runway shall also remain within  $\pm 5 \mu\text{a}$ .

\*The distance, measured on the ground, between the threshold and a point lying directly under the ILS reference datum will depend on the location of the glide slope and the glide slope angle.

TABLE VI - Comparison of the NSD values for each of the tested arrays  
 in the directions of the principal reflecting sources. Data based  
 on the theoretical distribution of sideband signal and the measured  
 course width at Boeing Field International

NSD (NORMALIZED SIDEBAND DIFFERENCE)

Angle From Front Course TO Reflecting Source		5.6° "C"	6.3° "B"	8.0° "A"	20° "D"	30° "D"	40° "D"
LOCALIZER	Measured Course Width	-	-	-	-	-	-
Type C6-1	7.0°	1.1	1.18	1.54	1.43	1.06	0.80
8 Loop*	4.0°	2.0	2.1	2.35	1.5	1.05	1.3
8 Loop**	4.7°	2.8**	3.0**	4.0**	1.6	1.24	.22**
Type 0	4.2°	1.63	1.81	1.90	0.46	0.5	0.19
Type 1A	4.3°	1.07	1.02	0.78	0.38	0.35	0.05
Type 1B (Course Array)	4.2°	0.95	0.86	0.57	.035/23°	.036/29°	.021/42°
Waveguide (Course Array)	4.0°	0.76	0.52	0.2	.045/21°	.07/27°	.044/38°
Type 2 (Course Array)	4.1°	0.23	.06	.01	.02/21°	.02/29°	.02/42°

\*Theoretical Data

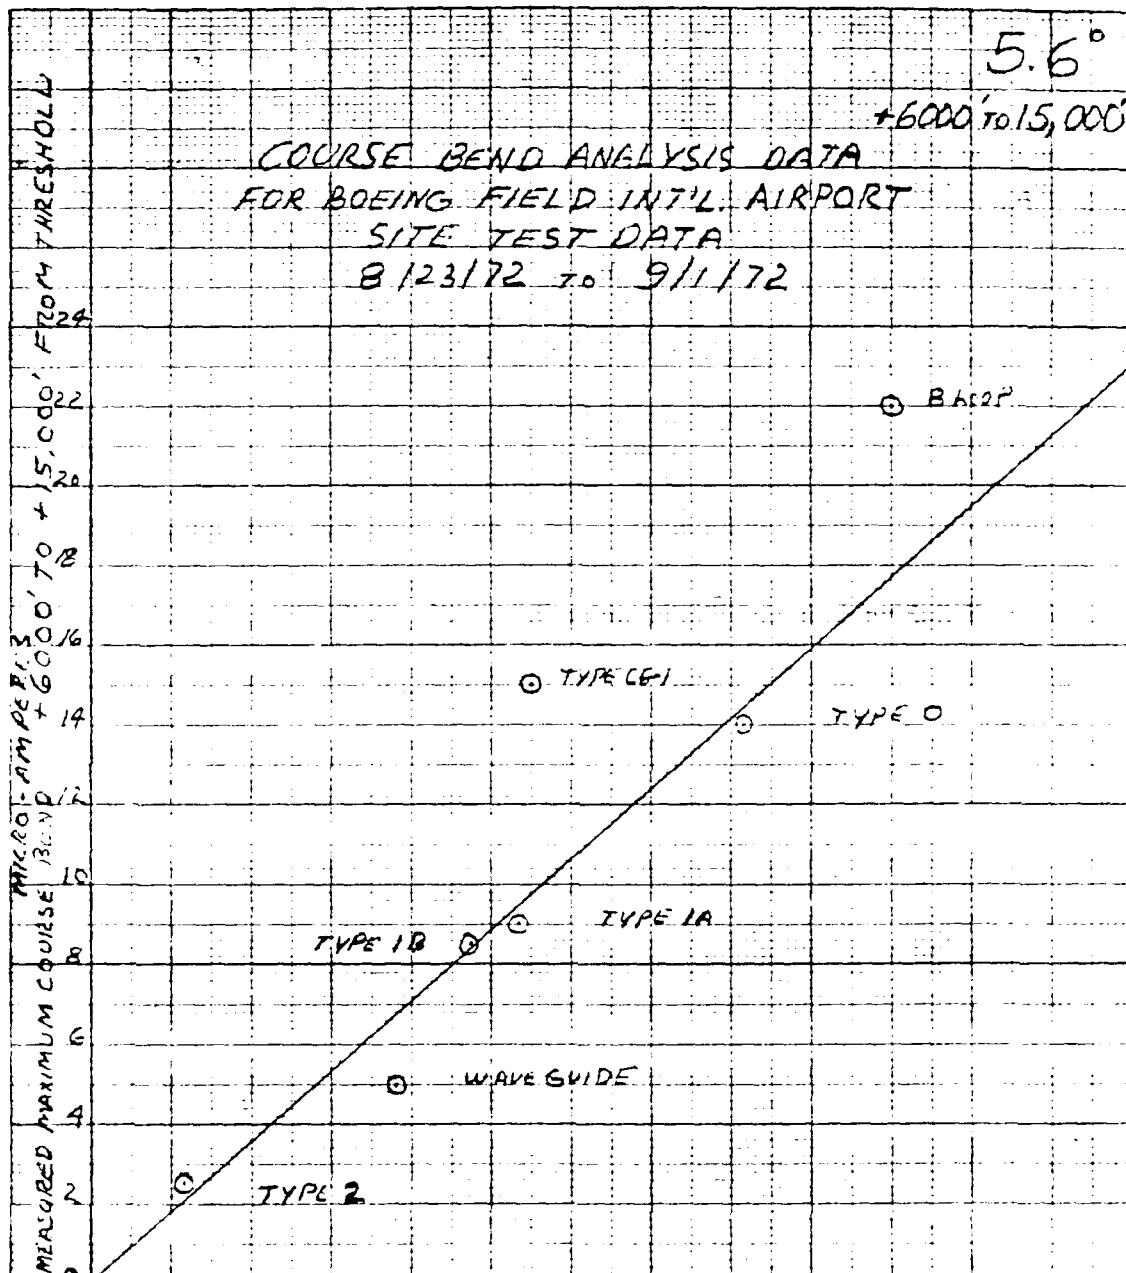

\*\*From flight data, see Dwg. A332-5032, the 0.22 NSD value at 40° is probably due to shielding by the hill. This value has no bearing on the value of the NSD controlling the reflection. The values of NSD at 5.6°, 6.3° and 8° are believed to be in error. These NSD values are taken from the measured SO pattern. The measured SO pattern, however, is questionable because of the difficulty in determining the correct AGC voltage levels when the high end of the receiver curve, greater than 100, rises as steeply as is indicated on Dwg. A332-5021 receiver SER 1051.
